# 1 Crack propagation analysis in bituminous mixtures reinforced by 2 different types of geogrids using digital image correlation

3  
4 In the rehabilitation of flexible pavements, the use of reinforcement by geogrids  
5 has substantially increased recently, aiming to extend the service life of  
6 pavements. This work evaluated the effect of fiberglass grid reinforcement on  
7 crack propagation of bituminous mixtures. To conduct the research, five different  
8 configurations of pre-notched beams constituted of two bituminous mixtures  
9 layers, with and without geogrid, were tested. Two different fiberglass geogrids,  
10 ultimate tensile strength (UTS) of 100 and 50kN/m, and emulsions as tack coat,  
11 made of bitumen pure and modify by polymer (SBS), were combined for the  
12 fabrication of three reinforced configurations. In addition, two unreinforced  
13 configurations were also fabricated. The first one was a single layer slab and the  
14 second one was bi-layered slab composed of two bituminous mixtures layers  
15 glued by a tack coat. The specimens were subjected to the four-point bending  
16 notched fracture (FPBNF) test, designed at the University of Lyon/ENTPE. A 3D  
17 Digital Image Correlation (DIC) technique was used to determine the strain field  
18 on specimen central length area during crack propagation. The results showed  
19 that the effect of geogrids was clearly noticeable when the specimen is subjected  
20 to high strain and the crack starts to propagate into the beams. DIC analysis  
21 allowed the observation of grid reinforcement effect on retarding the cracking  
22 propagation of bituminous mixtures layers.

23 Keywords: geogrid, reinforcement, bituminous mixtures, crack propagation

24 Subject classification codes:

## 25 26 1. Introduction

27 Interlayer reinforcement emerged in the 1930s as a solution to improve pavement  
28 structure performance [1]. Many interlayer systems have been analysed by the pavement  
29 community ever since, among the range of available commercialized products, such as sand

1 asphalt; SAMIs (Stress Absorbing Membrane Interlayers, composed by a blend of bitumen  
2 and rubber); fabrics or geotextiles; grids (steel, fiberglass and polymeric); and composites  
3 thereof [2, 3]. Recently, the use of geogrids has increased as a technical solution to rehabilitate  
4 pavements, extend their service life, and reduce maintenance costs [4]. Many works in the  
5 literature show that the reinforcement by geogrid can effectively retard the manifestation of  
6 cracking propagation in roadways [5-11]. Geogrid reinforcement was recommended since it  
7 could work as a strain-relieving component and effective to reflective cracking on the surface  
8 [5]. Reflective cracking is surface distress resulted from propagation of the cracks on an  
9 underneath damaged layer throughout the bituminous layer over it. In the cracking  
10 propagation analysis of bituminous mixtures, Fracture Mechanics concepts could be applied  
11 [12]. To evaluate the cracking resistance of reinforced bituminous mixtures in a prismatic  
12 beam shape in the laboratory different tests were proposed. Some authors used the three points  
13 bending test (3PBT) [8, 10, 13, 14]. Others used the four points bending test (4PBT) [8, 9, 15-  
14 18]. Other bending types of test could also be found in the literature [4, 7, 19-25].

15 In Italy, Pasquini et al. [7] conducted a work using geogrid-reinforced bituminous  
16 membranes as a method to prevent reflective cracking, for pavement rehabilitation. The  
17 specimens were composed of an old pavement layer and a new overlay with geocomposites  
18 within the interface. The tests called simulative reflective cracking (SRC) were performed in  
19 prismatic pre-notched specimens (3mm crack tip) produced in the laboratory. They were  
20 conducted at a temperature of 30°C and two amplitudes of loading (520 and 615N), with a rate  
21 of 21 cycles/min wheel rubber tire passing. From SRC tests, it was noticed that the  
22 geocomposites were effective in the anti-reflective cracking role since their performance was at  
23 least five times greater than the unreinforced specimen was. Canestrari et al. [8] performed  
24 3PBT at monotonic displacement controlled loading and 4PBT at cyclic flexural tensile lading.  
25 The tests were carried out on double-layered bituminous mixtures specimens with geogrid  
26 reinforcement and at a temperature of 20°C. The authors used a fiberglass geogrid with and  
27 without polymer coating and a carbon fiber geogrid. Concerning the 4PBT, the authors observed  
28 an increase of approximately 3-fold (fiberglass) and 4-fold (carbon fiber) at 1kN load level,

1 compared to the unreinforced beam fatigue life ( $N_f$ ). In addition, at a 1.5kN load level, 15-fold  
2 (fiberglass) and 6-fold (carbon fiber) was observed. Concerning 3PBT, the authors noticed that  
3 the fiberglass geogrid was more effective in retarding crack propagation from the bottom to the  
4 top of the specimen.

5 In France, located at the IFSTTAR APT facility, there is an outdoor circular carousel  
6 dedicated to full-scale pavement experiments. Thus, some work concerning geosynthetics  
7 reinforcement has been conducted in this facility. Horny et al. [26] constructed four  
8 pavement sections, three reinforced by fiberglass geogrid and one without reinforcement.  
9 Standard dual wheels applied the load of 65 kN and the loading speed was 6 rounds/minute  
10 (43 km/h). The temperatures varied between 20 and 28°C. In crack monitoring results, the  
11 reinforced section with the film as tack coat was the first to present cracks, followed by the  
12 unreinforced section. The reinforced section with the bitumen tack coat did not present cracks.  
13 Nguyen et al. [27] referring to the full-scale characterization using IFSTTAR APT facility  
14 concluded that the fiberglass geogrid, placed near the bottom of the bituminous mixture layer  
15 significantly improves the fatigue life. However, the bond quality between the geogrid and the  
16 bituminous mixture layers is essential to occur the reinforcement. Lastly, Arsenie et al. [17,  
17 28] studied the improvement in the fatigue resistance of bituminous mixtures by the utilization  
18 of coated fiberglass geogrid as reinforcement. The authors used the Four Point Bending Tests  
19 (4PBT) with beam containing two interface-geogrid, tested at a temperature of 10°C and  
20 frequency of 25Hz. In the first work, an increment in the fatigue life between 33.5% and  
21 45.5% was observed and in the second work, the increase in the fatigue life ( $N_f$ ) was 60%,  
22 based on fatigue Wohler curves.

23 Digital Image Correlation (DIC) technique was found to be a useful tool allowing the  
24 identification of different failure mechanisms during the crack propagation stage in reinforced  
25 beams and showing the strain-relieving capacity of geogrids [8, 13]. Recently, the DIC  
26 analysis has been successfully employed for the cracking propagation analysis of bending  
27 beam tests [9, 11, 18, 29-31]. This technique is more precise and gives more cracking  
28 information comparing to the classical analysis using strain gauges. Using DIC, the

1 information of a whole surface could be obtained, whereas, strain gauges are only able to  
2 measure data in local points.

3 Saride & Kumar [18] used DIC to analyse the 4PBT carried out in double-layer  
4 specimens reinforced with polyester grid (PET) and a glass-grid composite (GGC), and an  
5 unreinforced specimen. The specimens were composed by an extruded old asphalt as bottom  
6 layer and new asphalt overlay as top layers. Two pre-notch sizes were evaluated (25 and 40mm)  
7 along with specimens without it. Cyclic loading with 550kPa of magnitude at 25°C (room  
8 temperature) was used to obtain specimen fatigue properties. From DIC analysis, a tensile strain  
9 reduction was observed in the reinforced specimens of about 35-70% at the crack tip. Moreover,  
10 the fatigue life of the reinforced specimens was highly increased. Kumar & Saride [11]  
11 conducted a work aiming at evaluating the cracking resistance potential of double-layer  
12 reinforced beams. The test was carried out using the direct tensile strength test (DTT), at 20, 30,  
13 and 40°C with a constant vertical displacement rate of 1mm/min, and analysed using DIC. The  
14 results indicated an increase in the crack resistance potential due to the reinforcement,  
15 especially at 20°C. DIC analysis presented a reduction of tensile strain at the crack tip for  
16 reinforced specimens. The specimen with glass-grid reinforcement tested at 20°C presented a  
17 2.7 times reduction when compared to the single-layer specimen tested at the same temperature.

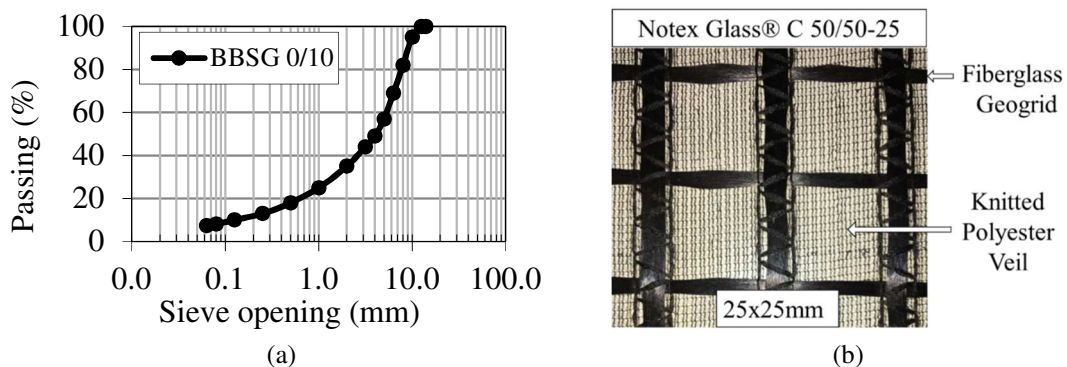

18 The literature evidenced an improvement in fatigue and crack propagation resistance  
19 due to the geogrid reinforcement, especially fiberglass geogrids. However, the characterization  
20 found were mostly at high temperatures (around 20°C), which difficult the interpretation of  
21 the cracking propagation phenomenon due to bituminous viscous behaviour. Hence, this work  
22 aimed at evaluating the effect of fiberglass geogrid reinforcement, presence, type, and tack  
23 coat, in crack propagation of bituminous mixtures layers. Moreover, the effect of geogrid  
24 ultimate tensile strength (UTS) and the SBS modification of the emulsion tack coat was  
25 evaluated. To this end, four-point bending notched fracture (FPBNF) tests designed at the  
26 University of Lyon/ENTPE [32] were carried out. To better analyse the tests, 3D Digital  
27 Image Correlation (DIC) technique was used to calculate the strain field on specimen central  
28 length area, during the crack propagation as well as its tip location.

1     **2. Materials and Experimental Protocol**

2     **2.1 Materials**

3     The French bituminous mixture BBSG 0/10 (*Béton Bitumineux Semi-Grenu*) was used to  
4     conduct the experimental campaign. This mixture was classified according to the European  
5     standards [33] and is normally used for surface courses. The BBSG 0/10 gradation curve is  
6     presented in Figure 1(a). It is composed of rhyodacite and rhyolitic mineral aggregates,  
7     limestone filler, and 20% of reclaimed asphalt pavement (RAP) containing 4.75% of aged  
8     bituminous binder. These aggregates were mixed with 4.40% of a new bituminous binder  
9     classified as 35/50 by its penetration. The total bituminous binder content (aged + new) in the  
10    mixture was 5.53% per total weight of the mixture.

11       The geogrids used to reinforce the bituminous mixtures were Notex Glass®, presented  
12    in Figure 1(b). It was composed of fiberglass yarns knitted to a light polyester veil, with a  
13    bituminous coating on both sides. The grids had a square mesh opening of 25mm in the two  
14    directions. Two types of geogrids were used in this work with UTS of 50kN/m (C 50/50) and  
15    100kN/m (C 100/100), in two perpendicular directions. These UTS were obtained at the failure  
16    point of 3% of strain in grids tensile characterization tests carried out for fabrication quality  
17    control. Lastly, a bituminous emulsion 160/220 by penetration [34] was used as a tack coat to  
18    glue the geogrid in the middle part of the slabs. A slab configuration was fabricated with  
19    bituminous emulsion modified by a styrene-butadiene-styrene (SBS) block copolymer.

20    Figure 1. Components of tested specimen: (a) bituminous mixture gradation curve; (b)  
21    fiberglass geogrid Notex Glass® C 50/50-25

1     **2.2 Specimens preparation**

2     Five different slab configurations, with dimensions 600 of length, 400 of width, and 150mm of  
3     depth, were compacted using a French wheel compactor [35]. Configuration A did not have an  
4     interface, while B, C, D, and E had interface and were denoted by bi-layered slabs.  
5     Configuration B had only the tack coat of emulsion made of pure bitumen at a residual rate of  
6     290g/m<sup>2</sup>. Whereas configurations C, D, and E were made with geogrid (50 and 100kN/m of  
7     UTS) and the tack coat (emulsion bitumen pure and with SBS) at a residual rate of 800g/m<sup>2</sup>, and  
8     were denoted by reinforced slabs.

9             The fabrication of configuration A slab followed the classical procedure described in  
10     the standard [35], since it was composed of a single layer slab, without interface/reinforcement.  
11     Concerning the reinforced slabs, they were fabricated by first compacting half-height slab  
12     (75mm) at a temperature of 180°C (for mixing and compaction) and cooling down for 24h.  
13     Then, the first tack coat application was done (400g/m<sup>2</sup>), followed by the geogrid placement.  
14     Afterward, the second tack coat application was done (400g/m<sup>2</sup>) on the geogrid surface. Finally,  
15     a period of 24h was waited so that the breaking process occurs in the emulsion before the  
16     second half-height (75mm) slab compaction. Figure 2 presents the steps of slab fabrication  
17     procedure.

1 Figure 2. Slab fabrication of reinforced bi-layered bituminous mixture: (a) First layer  
 2 compaction; (b) Emulsion first application; (c) Fiberglass geogrid placement, (d) Emulsion  
 3 second application, (e) Upper layer fabrication, and (f) Final compaction.

4 From each slab, three prismatic bars, with dimensions 550 of length, 70 of width, and  
 5 110mm of depth were sawn. Moreover, a 20mm long, 1mm thick notch was made in its centre-  
 6 bottom. Finally, to improve DIC accuracy, a speckle pattern was applied on the rectangular area  
 7 located in the central length of the beam, with a thin layer of white acrylic paint and a spray of  
 8 black paint on it. Figure 3 illustrates the slab composition and the final reinforced beam used for  
 9 the tests. Detailed information on the specimen composition, as well as air voids content  
 10 calculated in the bituminous mixture and are presented in Table 1. The air voids in reinforced  
 11 specimens were obtained by removing the grid and the tack coat weights and volumes from the  
 12 specimen specific gravity calculation.

13  
 14 Figure 3. Detail of beam specimen position from the slab, obtained from sawing and prepared  
 15 for testing

16 Table 1. Tested specimens composition and air voids in bituminous mixtures

Configuration	Specimen	Interface		Air Voids (in bituminous mixture layers) (%)
		Composition	Tack coat rate (residual binder)	
A	A1	Not applicable	Not applicable	6.3
	A2			7.8
B	B1	Pure bitumen	292g/m <sup>2</sup>	5.4
	B2			6.5

C	C1	Pure bitumen and GG 100kN/m		6.2
	C2			4.1
	C3			4.7
D	D1	Pure bitumen and GG	2×400g/m <sup>2</sup>	6.1
	D2	50kN/m		4.3
E	E1	SBS-modified bitumen and		3.7
	E2	GG 100kN/m		3.9

### 1     2.3     *Four-point bending notched fracture (FPBNF) test*

2     The test was performed in a servo-hydraulic press. The press produces axial loading from its  
3     actuator. The actuator displacement was measured by an integrated transducer and used for  
4     controlling the loading applied during the tests. The press was equipped with a load cell with  
5     50kN maximum capacity. Moreover, three Linear Variable Differential Transducers (LVDT)  
6     were placed on the top of the beam, two of them directly above the lower supports (LVDT1 and  
7     LVDT3) and another one in the beam centre length (LVDT2) to measure the vertical  
8     displacement in these three points. Beam's deflection was not only obtained with the LVDT2  
9     measurement but also using the LVDT1 and LVDT3 measurements, which allowed estimating  
10    the punching effect of the lower supports into the beam. Thus, beam deflection was calculated  
11    according to Equation (1).

$$Deflection = LVDT2 - \frac{LVDT1 + LVDT3}{2} \quad (1)$$

12         Figure 4 presents a scheme containing the devices used to perform the test. Four-point  
13    bending notched fracture (FPBNF) tests designed at the University of Lyon/ENTPE were  
14    carried out. More test details can be found in previous works [27, 32, 36]. A thermal chamber  
15    was coupled to the press [37, 38] allowing temperature control. The specimen surface  
16    temperature was measured using one thermal gauge (PT100 temperature probe) fixed on the  
17    specimen surface. Furthermore, during the presented experimental campaign, two added  
18    cameras (CCD Pike F-421B/C) targeting the sprayed area were positioned outside the thermal  
19    chamber. These two cameras allowed performing the 3-dimension DIC analysis.

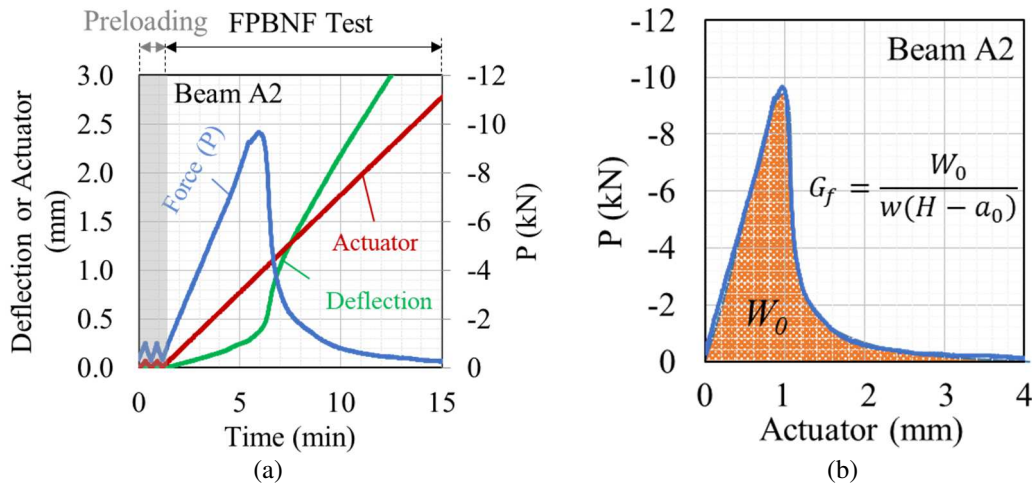

(a)

(b)

1 Figure 4. Experimental test device and procedure for FPBNF test: (a) scheme and measurement  
 2 device location; (b) Thermal chamber and cameras set up

3 The specimens were conditioned at  $-5^{\circ}\text{C}$  overnight in a freezer and transferred to the  
 4 press, where one additional hour of temperature conditioning at  $-5^{\circ}\text{C}$  was done. The FPBNF test  
 5 was performed at a constant rate of actuator displacement of  $0.2\text{mm}/\text{min}$ . The test was divided  
 6 into two steps. First, two “small” cycles of loading/unloading were performed at the same  
 7 displacement rate with a small force amplitude ( $1\text{kN}$  peak and  $0,3\text{kN}$  valley) to ensure the good  
 8 setting of contact between specimen and supports. Second, a constant rate of actuator  
 9 displacement loading was performed until the complete crack propagation throughout the  
 10 specimen height. Figure 5(a) presents a plot containing the actuator displacement input and the  
 11 force ( $P$ ) response measured during the test for sample A2. An energy approach was also used  
 12 to evaluate crack propagation resistance of different specimens’ configurations. In this  
 13 approach, the area below the curve force versus actuator displacement corresponds to the  
 14 necessary mechanical energy to propagate the crack throughout the specimen’s height. Figure  
 15 5(b) illustrates the area used for this calculation and presents the energy restitution rate ( $G_f$ )  
 16 equation, where  $W_0$  is the area below the curve,  $w$  is the beam width (m),  $H$  is the beam height  
 17 (m) (dimensions of beam’s section), and  $a_0$  is the pre-notch size (m).

1 Figure 5. Test on sample A2: (a) actuator displacement, force, and deflection versus time; (b)  
 2 force versus actuator displacement and the area below the curve ( $W_0$ ) used to calculate the  
 3 energy restitution rate ( $G_f$ )

### 4 3. Digital image correlation (DIC) analysis

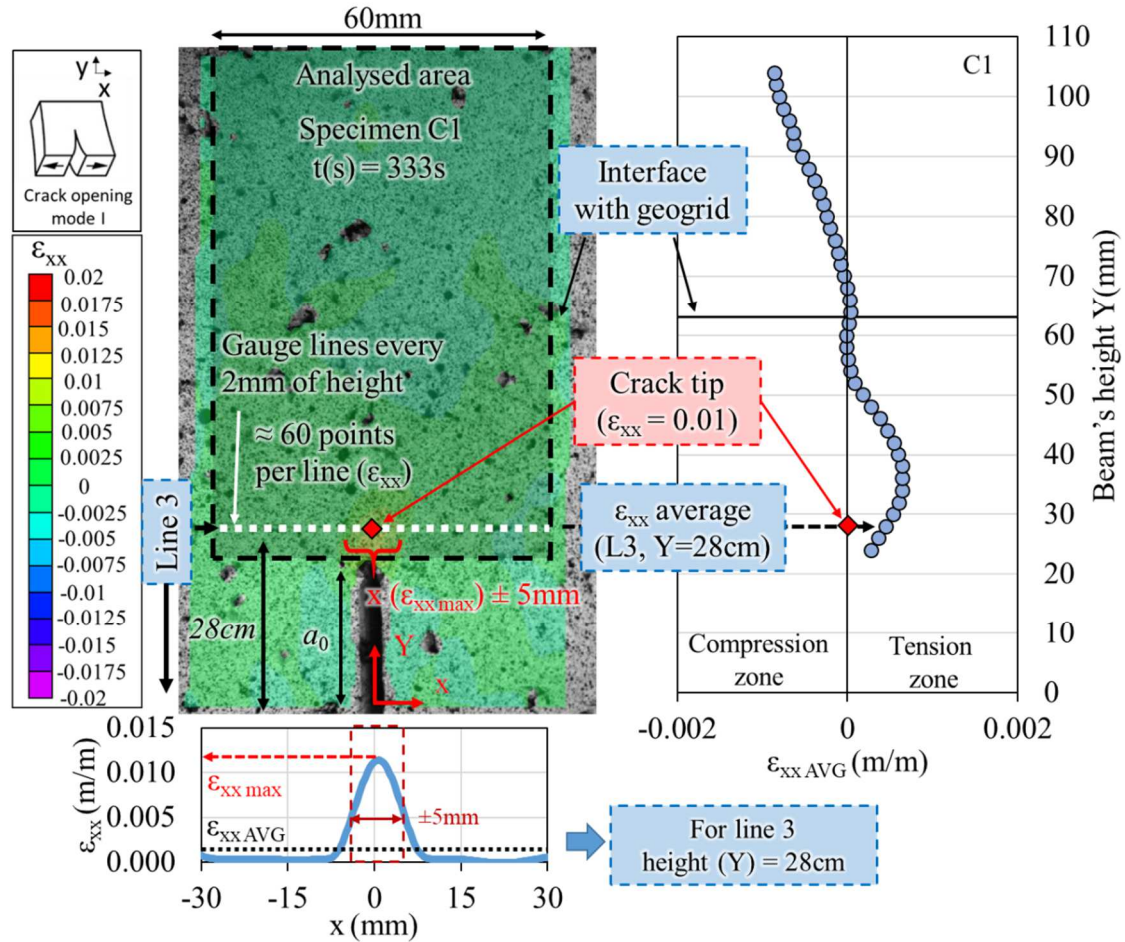

5 DIC is an optical and contactless measurement technique used to compute the displacement on  
 6 a specific area of analysis [39]. From simultaneous monochromatic digital images acquired  
 7 with the aid of two cameras, a 3D displacement field was obtained by image correlation. Each  
 8 picture is an arrangement of pixels in different shades of grey. The displacement was  
 9 calculated by comparing subsets of virtual squares containing a small amount of pixel in  
 10 original and deformed states at different instants of time [39-41]. The strain field is also  
 11 deduced by the derivation of displacement. The software VIC 3D 7 Correlated Solutions, Inc.  
 12 was employed to perform the image correlation treatment. For each test, one couple of pictures  
 13 (one from each camera) was taken every 3s during the tests. A subset size of 21 pixels and a  
 14 filter size of 15 pixels were used for DIC analysis in VIC 3D.

15 Using the software, horizontal lines were created every 2mm of specimen height  
 16 starting from the notch tip. The initial height of the crack tip was the notch size ( $a_0$ ). Each  
 17 virtual gauge line was composed of 100 virtual points, and for each point, the horizontal strain  
 18 ( $\epsilon_{xx}$ ) was calculated. A positive sign means an extension of the analysed point of the specimen  
 19 (tensile strain) while a negative sign stands for a contraction.

20 The cracking appearance criterion, useful for crack tip identification, was the same used  
 21 and validated considering back analysis in previous work at the University of Lyon/ENTPE

1 [37, 38]. It is given by the maximum boundary value,  $\varepsilon_{xx} = 0.01\text{m/m}$ . As soon as this value  
2 was measured in one (or more) point of the gauge line, the crack was considered passing this  
3 line (propagating higher in the beam). This allows following the crack tip during the test.  
4 Furthermore, for each virtual gauge line, the average strain ( $\varepsilon_{xx\text{ AVG}}$ ) of its points was calculated  
5 and plotted as a function of the specimens' height. As the crack propagates through the central  
6 region of the specimen, a reduction of points was applied and only the points presented within  
7 the central 60mm were considered in the calculation of ( $\varepsilon_{xx\text{ AVG}}$ ) and analysis. Figure 6 presents  
8 an explanation of the adopted analysis methodology and results at one instant during the test  
9 on specimen C, having a geogrid of 100kN tensile strength.

10 However, when the crack was open and its tip had already passed the analysed line, the  
11 strain measured from DIC could be imprecise leading to errors in the analysis. Thus, a  
12 correction in the  $\varepsilon_{xx\text{ AVG}}$  of the line in this situation was performed: all the points in the line  
13 located at  $\pm 5\text{mm}$  around the crack were removed from  $\varepsilon_{xx\text{ AVG}}$  calculation. In order to locate  
14 this range of points, the maximum strain measured ( $\varepsilon_{xx\text{ MAX}}$ ) is found for a given instant of time  
15  $t$ , and the coordinate  $x$  of the point containing  $\varepsilon_{xx\text{ MAX}}$  is used. Thus, if  $\varepsilon_{xx\text{ MAX}} \geq 0.01\text{m/m}$  (crack  
16 criterion), the removed points are those between the range of  $x \pm 5\text{mm}$  around the point of  $\varepsilon_{xx}$   
17  $\text{MAX}$ . Figure 6 illustrates the mentioned procedure.

1  
2 Figure 6. Explanation of procedure of analysis performed with Digital Image Correlation (DIC)  
3 technique (specimen C1, t=333s)

#### 4 4. Crack Propagation Test Results

##### 5 4.1 Force versus deflection curves

6 The Force versus Deflection curve (calculated using Equation 1) was plotted for the five tested  
7 specimens in Figure 7. Curve peak indicates approximately the crack initiation and from this  
8 point, the crack starts to propagate. Similar curves in this region confirmed that the presence of  
9 the geogrid did not noticeably influence the load peak value. This same result was observed in  
10 Canestrari [8].

11 It is possible to notice a difference between the reinforced specimens and the  
12 unreinforced ones in the post-peak part of the curve. The fiberglass geogrid improves the crack  
13 propagation resistance of bituminous mixtures. Concerning configuration A (no interface) and B  
14 (interface with bitumen pure), similar curves were observed, which indicates very similar

1 behaviour. Two different values of force in the plateau regime were observed in the reinforced  
 2 specimens: one for the geogrid with UTS of 50kN (D specimens) and another for the geogrid  
 3 UTS of 100kN (C and E specimens). The force plateau observed for C and E specimens was  
 4 approximately twice when compared to the one observed for specimens D, which was  
 5 consistent with the ratio between the UTS of them. In addition, the curves also indicated that  
 6 from 1.5mm of beam's deflection, most of the effort was taken by the geogrids. This result  
 7 indicated that the UTS of the geogrid directly influences the load capacity of the beam.

8  
 9 Figure 7. Force versus deflection curve results for tested specimens (cf. Table 1)

10 From the results of tests on specimens A and B without geogrid, presented in Figure 7,  
 11 it is clear that for deflection higher than about 2mm the bituminous layer(s) did not support any  
 12 load because the crack was propagated over the whole thickness. It is then possible to give an  
 13 evaluation of the geogrid effect during the tests C, D, and E, by assuming that only the geogrid  
 14 supports loading from this point (2mm of deflection). A calculation was done to verify this  
 15 hypothesis. The equilibrium of moments in the central section is written in Equation 2  
 16 considering that compressive force is supported by the upper bituminous mixture layer at a  
 17 given point located at a distance  $h$  of the geogrid (hinge in Figure 8). In the plateau regime, just  
 18 before total failure, the geogrid reaches its load strength ( $F_{GGfail}$ ). The ductile failure of the  
 19 geogrid can be mobilised as large strain values exist in this material. The maximum force  
 20 supported by the geogrid during the bending  $F_{GGfail}$  was calculated by considering that the grids  
 21 were subjected to their UTS, 50 and 100kN/m. Moreover, each specimen contained

1 approximately 3 yarns of the grid resisting the bending, and there were 40 yarns/m since their  
 2 mesh openings were 25mm. Thus,  $F_{GGfail}$  was 3.75kN for 50kN/m geogrid (configuration D) and  
 3 7.5kN for 100kN/m geogrid (configurations C and E). Equation 3 gives the expression of  $h$  in  
 4 the plateau regime,  $h_p$ . The obtained values are given in Table 2 for specimens C, D, and E.  
 5 These values are higher than 3cm and lower than 4cm, which is quite physically realistic and  
 6 could be considered as a validation of the simplified postulated hypothesis. This result indicates  
 7 that the force plateau of reinforced specimens was due to the geogrid mobilization at large  
 8 deflection during the test.

9  
 10 Figure 8. Illustration of four points bending beam pivoting around a hinge, supported only by  
 11 the geogrid.

$$F_{GGfail} \cdot h_p - 6 \cdot (P_p) = 0 \quad (2)$$

12 It comes on the plateau regime:

$$h_p = \frac{6 \cdot (P_p)}{F_{GGfail}} \quad (3)$$

13 Where  $P_p$  is the value of force obtained for the plateau regime taken at 0.2cm of deflection, and  
 14  $h_p$  is the hinge height in the plateau regime expressed in centimetres.

15 Table 2. Forces measured on the plateau regime (taken at 2mm of deflection) and corresponding  
 16 plateau pivot height ( $h_p$ )

Specimen	$P_p$ (kN)	$h_p$ (cm)
C1	3.7	3.0
C2	4.1	3.3
C3	4.0	3.2
D1	2.4	3.9
D2	2.5	4.0

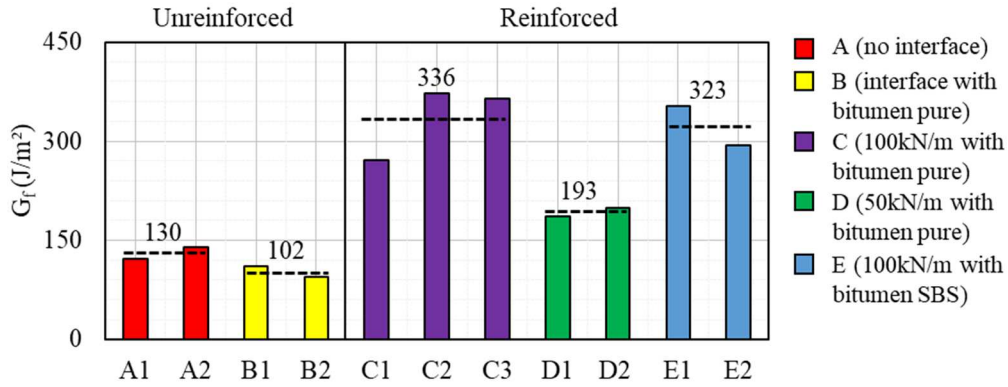

E1	4.0	3.2
E2	3.9	3.1

#### 4.2 Energy restitution rate

Figure 9 presents the energy restitution rate ( $G_f$ ) obtained for all tested specimens. This result represents the mechanical energy to propagate the crack throughout the specimen's height. Thus, it was expected higher  $G_f$  in the tests of specimens reinforced by geogrid. The results obtained concerning unreinforced specimens (configurations A and B) presented much lower  $G_f$  than the reinforced specimens (configurations C, D, and E). Configuration C (100kN/m and pure bitumen tack coat) needed approximately 2.6 times more energy to propagate the crack in relation to A (no interface) and 3.3 times more in relation to B (interface with pure bitumen tack coat). Concerning configuration D (50kN/m and pure bitumen tack coat), approximately 1.5 times more in relation to A and 1.9 times more in relation to B were obtained. Lastly, in configuration E (100kN/m and bitumen-SBS tack coat) the relations obtained were 2.5 times more to A and 3.2 times more to B. These results indicated that more fracture energy is required for reinforced specimens due to geogrid presence. This parameter could be associated with the reflective cracking resistance of reinforced bituminous mixtures layers. Thus, the results suggested that geogrid reinforcement was effective to combat reflective cracking in bituminous mixtures layers. Moreover, the unreinforced bi-layer specimen (configuration B) performed 22% lower when compared to the single-layered specimens (configuration A). This performance decrease suggested that the interface presence weakened the specimen performance against reflective cracking, and showed up the importance of high-quality interface adhesion. Comparing the reinforced specimens, configurations C and E needed a similar amount of energy to propagate the crack and approximately 1.7 times more than D. This result indicated that the UTS of the geogrid influenced the performance of the specimens much more than the type of tack coat used. UTS could be translated to stiffness since both geogrids failed at the same strain level (3%) in their tensile characterization. Therefore, higher stiffness resulted in better performance to reduce reflective cracking in bituminous mixtures layers, similar

1 conclusion as obtained by Kumar and Saride [11].

2  
3 Figure 9. Energy restitution rate ( $G_f$ ) obtained for the tested specimens

4 **4.3 DIC analysis**

5 DIC measurement was verified considering a strict calibration process using LVDT. This step is  
6 not detailed as it is a compulsory step included in all good experimental campaigns. An example  
7 of comparison between LVDT and DIC measurements concerning specimen A2 is given in the  
8 appendix. Figure 10 presents images of all tested specimens at the end of their respective tests,  
9 achieved when the force measured decreased to -0.5kN, to observe the crack shape. Concerning  
10 unreinforced specimens (configurations A and B), it can be observed that the cracks presented a  
11 rather straight vertical path from the bottom to the top. The same observation can be made  
12 concerning the specimens of configuration E and specimen C1. However, concerning the other  
13 two specimens of configuration C and the specimens of configuration D, the crack had his path  
14 deviated at the interface by the geogrid.

1 Figure 10. Treated images of tested specimens at the end of crack propagation

2 Figure 11(a) presents the evolution of the crack tip height ( $a$ ) as a function of the beam  
3 deflection for unreinforced specimens A (no interface) and B (interface with pure bitumen tack  
4 coat). For these specimens, overlapped curves with no discontinuity were obtained. Similar to  
5 the results of force versus deflection, the presence of a tack-coat-only interface did not affect the  
6 evolution of crack tip height and configuration B yields identical curves as configuration A,  
7 despite the difference obtained with the energy approach discussed in the previous section.

8 Figure 11(b) presents the results for unreinforced specimens but includes also the  
9 results obtained in the tests conducted with specimens of configuration C (100kN/m and pure  
10 bitumen tack coat). The curve for C1 was similar to the curves for unreinforced specimens.  
11 However, concerning specimens C2 and C3, a clear cracking retard was observed since the  
12 beams presented more deflection before crack propagation from the interface to the upper layer.  
13 At the interface level, the deflection measured for the unreinforced specimens was  
14 approximately 0.7mm, whereas C2 and C3 measured approximately 1.1mm, which means 1.6  
15 times higher, comparing them. This is indicative of crack retarding due to the presence of  
16 geogrid.

17 Figure 11(c) presents the graphic of unreinforced specimens but including the results  
18 obtained in the tests conducted with specimens of configuration D (50kN/m and pure bitumen  
19 tack coat). Again, distinct curve shapes were observed. For both D1 and D2, a discontinuity was  
20 observed when the crack reached the interface level. From this point, a cracking delay was  
21 noticeable. The deflection measured in the tests of D specimens was approximately 1.05mm  
22 when the crack reached the interface level, which was 1.5 times higher than specimens A and B  
23 at the same point of analysis.

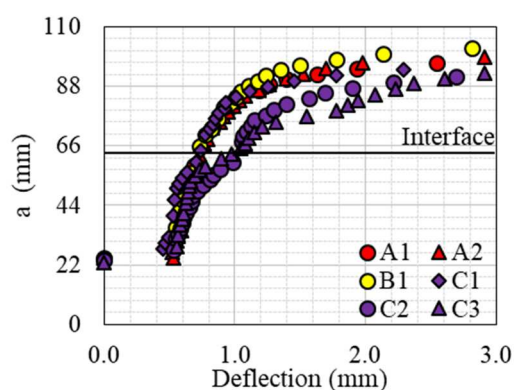

24 Lastly, Figure 11(d) presents the plot for unreinforced specimens but including the  
25 results obtained in the tests conducted with specimens of configuration E (100kN/m and SBS-  
26 modified tack coat). In this case, the curves presented a similar shape to specimens A and B,  
27 even if the configuration E specimens show slightly higher deflection than the unreinforced

1 specimens do. The deflection measured for configuration E results were approximately 0.85mm  
 2 when the crack reached the interface level, which is 1.2 times higher than specimens A and B at  
 3 the same point of analysis.

4 It should be noted in Figure 11 a good repeatability of the tests for each configuration  
 5 since the tests resulted in overlapped curves of specimens with the same configuration (except  
 6 specimen C1). To conclude, each time the crack path had only a little deviation from the vertical  
 7 direction of propagation (seen in Figure 10), the same crack height versus deflection curve was  
 8 observed (tests A, B, C1, and E). Thus, the result presented in Figure 11 was directly related to  
 9 the ability of interface-geogrid to deviate the crack path during its vertical propagation (results  
 10 of beams C2, C3, and D). As a result, the crack height versus deflection curve shows a  
 11 discontinuity at the interface, meaning that the propagation of the crack in the upper layer was  
 12 delayed. However, this ability depends on the characteristics of the used tack coat and was not  
 13 observed for the SBS modified tack coat (configuration E).

(a)

(b)

(c)

(d)

1 Figure 11. Crack tip height “a” versus beam deflection: (a) unreinforced configurations  
 2 containing interface (B) and no interface (A), (b) configuration C (geogrid of 100kN/m)  
 3 together with unreinforced configurations, (c) configuration D (geogrid of 50kN/m) together  
 4 with unreinforced configurations, and (d) configuration E (geogrid of 100kN/m with SBS-  
 5 modified tack coat) together with unreinforced configurations

6 Figure 12(a) presents the  $P$  versus deflection curve obtained for unreinforced specimen  
 7 B1 (interface with pure bitumen tack coat). In this figure, three specific locations were chosen:  
 8 (1) peak of the curve, deflection = 0.3mm,  $t = 306s$ , (2) Post peak at a deflection = 0.56mm,  $t =$   
 9 333s and (3) Post peak at a deflection = 1mm,  $t = 360s$ . The first point represents the moment  
 10 when the crack was about to start to propagate, the second one was the moment where the crack  
 11 tip reached the interface, and the last one represented a moment when the crack was almost at  
 12 the end of the propagation.

13 Figure 12(b) presents the DIC analysis at point 1. The DIC treated image (left) and the  
 14 plot of maximum horizontal strain ( $\epsilon_{xx \text{ MAX}}$ ) (right) show a strain concentration at the tip of the  
 15 pre-notch. Figure 12(c) presents the analysis at point 2. At this stage, the crack propagated and  
 16 the tip reached approximately a height of 66mm. At this point, in both graphics, average strain  
 17 ( $\epsilon_{xx \text{ AVG}}$ ) (middle), and maximum strain ( $\epsilon_{xx \text{ MAX}}$ ) (right), a gap was observed between the curves  
 18 below and above the interface. This gap indicates a slight slip at the interface between the  
 19 bituminous mixture layers when the crack tip was reached. Figure 12(d) presents the analysis at  
 20 point 3. In this case, the crack propagated in the upper layer, and its tip reached approximately  
 21 88mm of height. In this last point, the gap disappeared from the average strain graphic.  
 22 However, in the maximum strain graphic, the gap was bigger.

1 Figure 12. Results for test on unreinforced specimen B1 (interface with pure bitumen tack coat):  
 2 a) Global load versus deflection curve; b, c, d) Crack and horizontal strain field obtained with  
 3 DIC analysis (left); average strain values ( $\epsilon_{xx \text{ AVG}}$ ) (middle) and maximum strain values ( $\epsilon_{xx \text{ MAX}}$ )  
 4 (right) versus beam height for positions 1 (b), 2 (c) and 3(d) indicated in (a).

5           Regarding a reinforced specimen, the previous analysis was performed on sample D2  
 6 (50kN/m and pure bitumen). Figure 13(a) presents the obtained curve  $P$  versus deflection. In  
 7 this figure, the four points chosen for the analysis of average and maximum strains throughout  
 8 the beam height are indicated: (1) peak point, deflection = 0.25mm,  $t = 306$ s, (2) post-peak point  
 9 at a deflection = 0.45mm,  $t = 348$ s, (3) post-peak point at a deflection = 1mm,  $t = 456$ s, and (4)

1 post peak-point at a deflection = 2.6mm,  $t = 804s$ . The first point represents the moment when  
2 the crack was about to start the propagation, the second one was the moment when the geogrid  
3 started being mobilized, the third one was the beginning of force plateau period, and the last one  
4 was the end of the force plateau period.

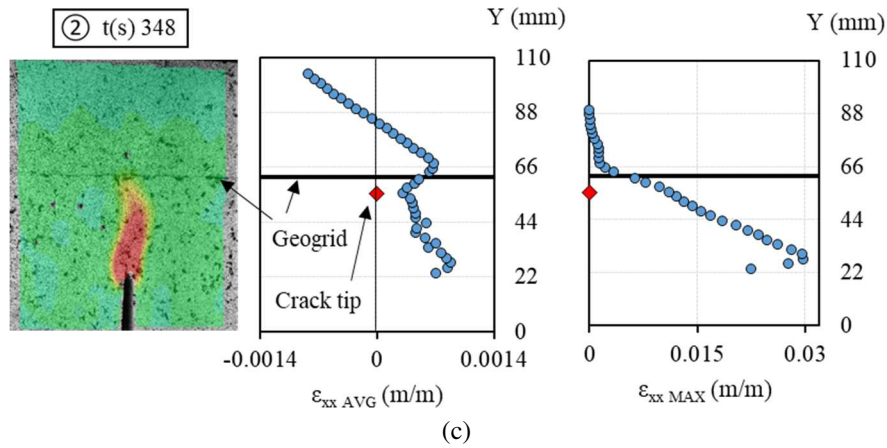

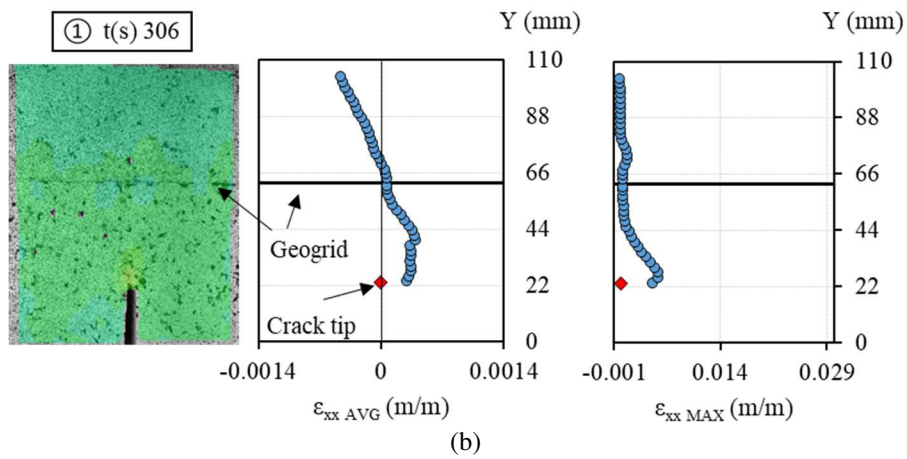

5 Figure 13(b) presents the DIC analysis at point 1. The average strain at the interface  
6 level at this moment of the test was zero because the interface with geogrid was placed very  
7 close to the neutral axis of the beam. This result shows that the geogrid was not mobilized until  
8 the beginning of crack propagation. Moreover, it explained why the results obtained for all the  
9 specimens, regardless of their constitution were the same until the peak of force.

10 Figure 13(c) presents the analysis at point 2. In this case, the crack propagated and its  
11 tip reached approximately 29mm of height. Concerning the average strain graphic, the upper  
12 layer behaved as a beam subjected to bending alone (triangular stress distribution). However, a  
13 high strain level at the interface indicates that the geogrid was mobilized at this point. From the  
14 maximum strain graphic, it is noticeable that the strain was more concentrated in the lower layer  
15 than in the upper layer. Moreover, there is no gap caused by the interface suggesting that there  
16 was no slip in the interface.

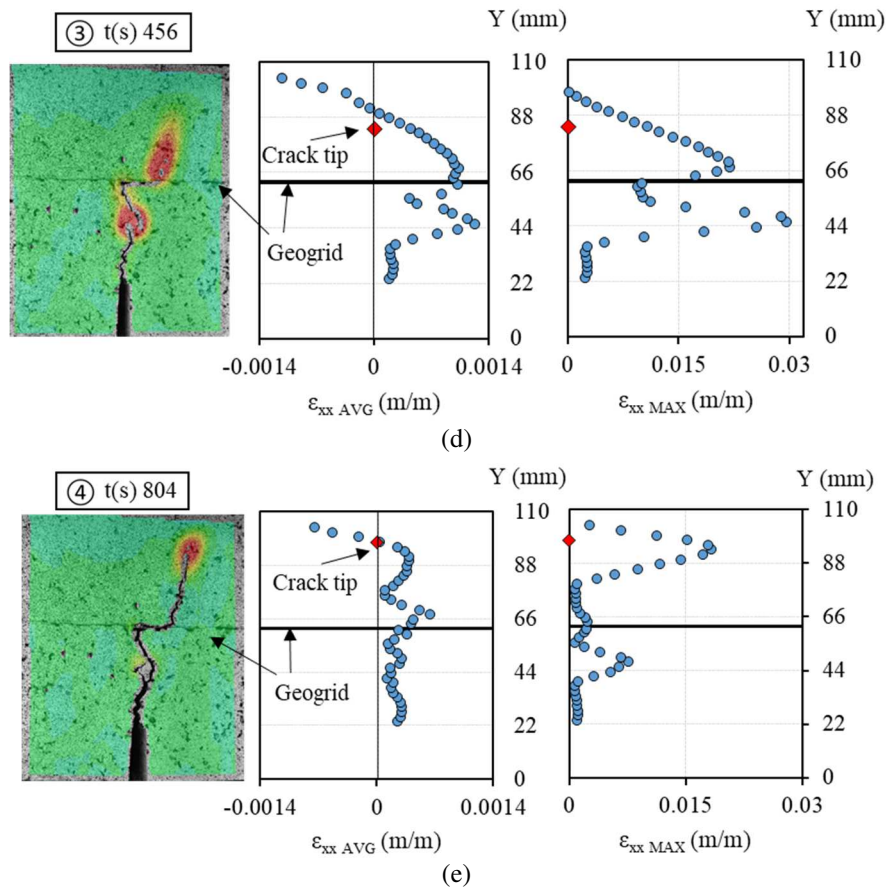

17 Figure 13(d) presents the analysis at point 3. At this point, the crack propagated and its  
18 tip reached approximately 77mm of height. When the crack tip reached the interface, it was  
19 deviated from its original path due to the geogrid presence. At this moment, it was noticeable  
20 that even when the crack tip passed through the geogrid, the strain value (extension) is very high  
21 at the interface level, it was approximately 0.001m/m on average with a maximum of  
22 0.017m/m. This result was another evidence that the geogrid was highly mobilized during the  
23 force plateau and, therefore, being responsible for it.

24 Finally, Figure 13(e) presents the analysis at point 4. At this point, the crack propagated  
25 and its tip reached approximately 97mm of height. At this moment, the geogrid was the one  
26 responsible for supporting the load since no more strain could be measured on the bituminous  
27 mixture except in the free of the crack upper part of the specimen where high compressive strain  
28 exists indicating compression stress. This visual DIC analysis validates the simplified

1 hypotheses made previously (Equation 3). Table 2 the hinge is located at 3.9 cm from the  
 2 geogrid, which corresponds to the value obtained in Figure 13(e). The decrease of load P after  
 3 point 4 was related to the geogrid deterioration. At the end of the test, it was observed that the  
 4 geogrid was broken.

1 Figure 13. Results for test on specimen D2 (interface with 50 kN/m geogrid): a) Global load  
 2 versus deflection curve; b, c, d, e) Crack and horizontal strain field obtained with DIC analysis  
 3 (left); average strain values ( $\epsilon_{xx\text{ AVG}}$ ) (middle) and maximum strain values ( $\epsilon_{xx\text{ MAX}}$ ) (right) versus  
 4 beam height for positions 1 (b), 2 (c), 3(d) and 4(e) indicated in (a).

## 5. Conclusions and Recommendations

6 This work presented an evaluation of the effect of fiberglass geogrid reinforcement to  
 7 reduce de reflective cracking of bituminous mixtures layers. Moreover, geogrid ultimate tensile  
 8 strength (UTS) and the SBS modification of the emulsion bitumen (tack coat) were also  
 9 evaluated. The major conclusions are listed below:

- 10 • The presence of an interface, containing or not a geogrid, does not influence the peak
- 11 load, which is an indication of crack propagation initiation.
- 12 • Geogrids increase the resistance of the beam to crack propagation. A plateau zone is
- 13 observed where the load is mainly controlled by geogrid strength (crack-bridging). The
- 14 increase in geogrid UTS increased the plateau value for the geogrids adopted in the
- 15 study.

- 1 • Digital Image Correlation (DIC) analysis was useful and efficient for calculating the  
2 strain field and the crack tip position during the test. It allowed explaining what  
3 physically happens on the beam surface around crack location thanks to a powerful  
4 visual tool.
- 5 • Even after the crack has crossed the interface, the geogrid was still highly capable of  
6 supporting the load. The crack could propagate for more than 2 cm over the interface  
7 before the geogrid breaks.
- 8 • The non-linearity observed in  $\varepsilon_{xx\ AVG}$  as a function of crack height during the test was  
9 caused by geogrid influence, interface thickness, and tack coat quantity and quality.
- 10 • Modelling and quantification of the plateau phenomenon observed with the geogrid  
11 interface were proposed. The simple postulated hypotheses were validated by the DIC  
12 analysis.

13 Following these conclusions, some recommendations and perspectives for future  
14 research are presented hereafter:

- 15 • Cyclic loading test at a temperature of 10°C and a frequency of 10Hz should be  
16 performed to assess the fatigue cracking behaviour of reinforced specimens
- 17 • Construction and monitoring of a field trial reinforced by the fiberglass geogrids and  
18 emulsions tack coat used in this study, to validate the results obtained.

## 1 List of notations and abbreviations

$a$	crack tip height, mm
$a_0$	pre-notch size, mm
BBSG	<i>béton bitumineux semi-grenu</i> (semi-coarse hot asphalt mixture)
DIC	digital image correlation
$F_{GGfail}$	maximum force supported by the geogrid during the bending, kN
FPBNF	four-point bending notched fracture
$G_f$	energy restitution rate, J/m <sup>2</sup>
GG	geogrid
$H$	beam height, m
$h$	distance between the hinge and interface, cm
$h_p$	distance between the hinge and interface in the plateau regime, cm
LVDT	linear variable differential transducers
$P$	force, kN
$P_p$	value of force obtained for the plateau regime, kN
RAP	reclaimed asphalt pavement
SBS	styrene-butadiene-styrene
UTS	ultimate tensile strength
$w$	beam width, m
$W_0$	area below the curve P vs Actuator
<i>Greek symbols</i>	
$\epsilon_{xx}$	horizontal strain
$\epsilon_{xx\ AVG}$	average strain for a virtual gauge line
$\epsilon_{xx\ MAX}$	maximum strain measured on a virtual gauge line
